Homework 6: Ensemble Methods

Due: Monday, May 1st, at 10pm (Submit via Gradescope)

Instructions: Your answers to the questions below, including plots and mathematical work, should be submitted as a single PDF file. It's preferred that you write your answers using software that typesets mathematics (e.g. L^AT_EX, L_AT_EX, or MathJax via iPython), though if you need to you may scan handwritten work. You may find the [minted](#) package convenient for including source code in your L^AT_EX document. If you are using L_AT_EX, then the [listings](#) package tends to work better.

1 Gradient Boosting Machines

Recall the general gradient boosting algorithm¹, for a given loss function ℓ and a hypothesis space \mathcal{F} of regression functions (i.e. functions mapping from the input space to \mathbf{R}):

1. Initialize $f_0(x) = 0$.
2. For $m = 1$ to M :

(a) Compute:

$$\mathbf{g}_m = \left(\left. \frac{\partial}{\partial f(x_j)} \sum_{i=1}^n \ell(y_i, f(x_i)) \right|_{f(x_i)=f_{m-1}(x_i), i=1, \dots, n} \right)_{j=1}^n$$

(b) Fit regression model to $-\mathbf{g}_m$:

$$h_m = \arg \min_{h \in \mathcal{F}} \sum_{i=1}^n ((-\mathbf{g}_m)_i - h(x_i))^2.$$

(c) Choose fixed step size $\nu_m = \nu \in (0, 1]$, or take

$$\nu_m = \arg \min_{\nu > 0} \sum_{i=1}^n \ell(y_i, f_{m-1}(x_i) + \nu h_m(x_i)).$$

(d) Take the step:

$$f_m(x) = f_{m-1}(x) + \nu_m h_m(x)$$

¹Besides the lecture slides, you can find an accessible discussion of this approach in <http://www.saedsayad.com/docs/gbm2.pdf>, in one of the original references <http://statweb.stanford.edu/~jhf/ftp/trebst.pdf>, and in this review paper <http://web.stanford.edu/~hastie/Papers/buehlmann.pdf>.

3. Return f_M .

In this problem we'll derive two special cases of the general gradient boosting framework: L_2 -Boosting and BinomialBoost.

1. Consider the regression framework, where $\mathcal{Y} = \mathbf{R}$. Suppose our loss function is given by

$$\ell(\hat{y}, y) = \frac{1}{2} (\hat{y} - y)^2,$$

and at the beginning of the m 'th round of gradient boosting, we have the function $f_{m-1}(x)$. Show that the h_m chosen as the next basis function is given by

$$h_m = \arg \min_{h \in \mathcal{F}} \sum_{i=1}^n [(y_i - f_{m-1}(x_i)) - h(x_i)]^2.$$

In other words, at each stage we find the weak prediction function $h_m \in \mathcal{F}$ that is the best fit to the residuals from the previous stage. [Hint: Once you understand what's going on, this is a pretty easy problem.] **Solution:**

The i^{th} component of \mathbf{g}_m is computed as the partial derivative of $\ell(f(x_i), y_i)$ with respect to $f(x_i)$ at $f(x_i) = f_{m-1}(x_i)$.

$$\begin{aligned} \partial_{f(x_i)} \ell(f(x_i), y_i) &= \partial_{f(x_i)} \left[\frac{1}{2} (f(x_i) - y_i)^2 \right] \\ &= f(x_i) - y_i \end{aligned}$$

Evaluating this at $f(x_i) = f_{m-1}(x_i)$ we get $f_{m-1}(x_i) - y_i$. Thus the expression for \mathbf{g}_m is

$$\mathbf{g}_m = (f_{m-1}(x_i) - y_i)_{i=1}^n.$$

Thus,

$$h_m = \arg \min_{h \in \mathcal{F}} \sum_{i=1}^n ((-\mathbf{g}_m)_i - h(x_i))^2 = \arg \min_{h \in \mathcal{F}} \sum_{i=1}^n [(y_i - f_{m-1}(x_i)) - h(x_i)]^2.$$

2. Now let's consider the classification framework, where $\mathcal{Y} = \{-1, 1\}$. In lecture, we noted that AdaBoost corresponds to forward stagewise additive modeling with the exponential loss, and that the exponential loss is not very robust to outliers (i.e. outliers can have a large effect on the final prediction function). Instead, let's consider the logistic loss

$$\ell(m) = \ln(1 + e^{-m}),$$

where $m = yf(x)$ is the margin. Similar to what we did in the L_2 -Boosting question, write an expression for h_m as an argmin over \mathcal{F} . **Solution:**

Proceeding as in the previous question, we get

$$\mathbf{g}_m = \left(\frac{-y_i}{1 + e^{y_i f_{m-1}(x_i)}} \right)_{i=1}^n$$

and,

$$h_m = \arg \min_{h \in \mathcal{F}} \sum_{i=1}^n ((-\mathbf{g}_m)_i - h(x_i))^2 = \arg \min_{h \in \mathcal{F}} \sum_{i=1}^n \left[\left(\frac{y_i}{1 + e^{y_i f_{m-1}(x_i)}} \right) - h(x_i) \right]^2.$$

2 From Margins to Conditional Probabilities²

Let's consider the classification setting, in which $(x_1, y_1), \dots, (x_n, y_n) \in \mathcal{X} \times \{-1, 1\}$ are sampled i.i.d. from some unknown distribution. For a prediction function $f : \mathcal{X} \rightarrow \mathbf{R}$, we define the **margin** on an example (x, y) to be $m = yf(x)$. Since our class predictions are given by $\text{sign}(f(x))$, we see that a prediction is correct iff $m(x) > 0$. We have said we can interpret the magnitude of the margin $|m(x)|$ as a measure of confidence. However, it is not clear what the “units” of the margin are, so it is hard to interpret the magnitudes beyond saying one prediction is more or less confident than another. In this problem, we investigate how we can translate the margin into a conditional probability, which is much easier to interpret. In other words, we are looking for a mapping $m(x) \mapsto p(y = 1 | x)$.

In this problem we will consider margin-based losses. A loss function is a **margin-based loss** if it can be written in terms of the margin $m = yf(x)$. We are interested in how we can go from an empirical risk minimizer of a margin loss, $\hat{f} = \arg \min_{f \in \mathcal{F}} \sum_{i=1}^n \ell(y_i f(x_i))$, to a conditional probability estimator $\hat{\pi}(x) \approx p(y = 1 | x)$. Our approach will be to try to find a way to use the Bayes prediction function³ $f^* = \arg \min_f \mathbb{E}_{x,y} [\ell(yf(x))]$ to get the true conditional probability $p(y = 1 | x)$, and then apply the same mapping to the empirical risk minimizer. While there is plenty that can go wrong with this “plug-in” approach (primarily, the empirical risk minimizer from a hypothesis space \mathcal{F} may be a poor estimate for the Bayes prediction function), it is at least well-motivated, and it can work well in practice. And **please note** that we can do better than just hoping for success: if you have enough validation data, you can directly assess how well “calibrated” the predicted probabilities are. This blog post has some discussion of calibration plots: <https://jmetzen.github.io/2015-04-14/calibration.html>.

It turns out it is straightforward to find the Bayes prediction function f^* for margin losses, at least in terms of the data-generating distribution: For any given $x \in \mathcal{X}$, we'll find the best possible prediction \hat{y} . This will be the \hat{y} that minimizes

$$\mathbb{E}_y [\ell(y\hat{y}) | x].$$

If we can calculate this \hat{y} for all $x \in \mathcal{X}$, then we will have determined $f^*(x)$. We will simply take

$$f^*(x) = \arg \min_{\hat{y}} \mathbb{E}_y [\ell(y\hat{y}) | x].$$

Below we'll calculate f^* for several loss functions. It will be convenient to let $\pi(x) = \mathbb{P}(y = 1 | x)$ in the work below.

1. Write $\mathbb{E}_y [\ell(yf(x)) | x]$ in terms of $\pi(x)$ and $\ell(f(x))$. [Hint: Use the fact that $y \in \{-1, 1\}$.]

Solution:

$$\mathbb{E}_y [\ell(yf(x)) | x] = \ell(f(x)) \pi(x) + \ell(-f(x)) [1 - \pi(x)]$$

²This problem is based on Section 7.5.3 of Schapire and Freund's book *Boosting: Foundations and Algorithms*.

³In this context, the Bayes prediction function is often referred to as the “population minimizer.” In our case, “population” refers to the fact that we are minimizing with respect to the true distribution, rather than a sample. The term “population” arises from the context where we are using a sample to approximate some statistic of an entire population (e.g. a population of people or trees).

2. Show that the Bayes prediction function $f^*(x)$ for the exponential loss function $\ell(y, f(x)) = e^{-yf(x)}$ is given by

$$f^*(x) = \frac{1}{2} \ln \left(\frac{\pi(x)}{1 - \pi(x)} \right)$$

and, given the Bayes prediction function f^* , we can recover the conditional probabilities by

$$\pi(x) = \frac{1}{1 + e^{-2f^*(x)}}.$$

[Hint: Differentiate the expression in the previous problem with respect to $f(x)$. To make things a little less confusing, and also to write less, you may find it useful to change variables a bit: Fix an $x \in \mathcal{X}$. Then write $p = \pi(x)$ and $\hat{y} = f(x)$. After substituting these into the expression you had for the previous problem, you'll want to find \hat{y} that minimizes the expression. Use differential calculus. Once you've done it for a single x , it's easy to write the solution as a function of x .]

Solution: Fix x , then we want to find \hat{y} minimizing $pe^{-\hat{y}} + (1-p)e^{\hat{y}}$. Our first order condition is

$$\begin{aligned} \partial_{\hat{y}} (pe^{-\hat{y}} + (1-p)e^{\hat{y}}) &= pe^{-\hat{y}} - (1-p)e^{\hat{y}} = 0 \\ \iff \frac{p}{1-p} &= e^{2\hat{y}} \end{aligned}$$

Rearranging this expression we get

$$p = \frac{e^{2\hat{y}}}{1 + e^{2\hat{y}}} = \frac{1}{1 + e^{-2\hat{y}}}.$$

Manipulating it a different way, we get

$$\hat{y} = \frac{1}{2} \ln \left(\frac{p}{1-p} \right).$$

3. Show that the Bayes prediction function $f^*(x)$ for the logistic loss function $\ell(y, f(x)) = \ln(1 + e^{-yf(x)})$ is given by

$$f^*(x) = \ln \left(\frac{\pi(x)}{1 - \pi(x)} \right)$$

and the conditional probabilities are given by

$$\pi(x) = \frac{1}{1 + e^{-f^*(x)}}.$$

Again, we may assume that $\pi(x) \in (0, 1)$.

Solution: Fix x , then we want to find \hat{y} minimizing $p \ln(1 + e^{-\hat{y}}) + (1-p) \ln(1 + e^{\hat{y}})$. Our

first order condition is

$$\begin{aligned}
\partial_{\hat{y}} (p \ln(1 + e^{-\hat{y}}) + (1-p) \ln(1 + e^{\hat{y}})) &= \frac{-pe^{-\hat{y}}}{1 + e^{-\hat{y}}} + \frac{(1-p)e^{\hat{y}}}{1 + e^{\hat{y}}} = 0 \\
\iff \frac{(1-p)e^{\hat{y}}}{1 + e^{\hat{y}}} &= \frac{p}{1 + e^{\hat{y}}} \\
\iff e^{\hat{y}} &= \frac{p}{1-p} \\
\iff \hat{y} &= \ln\left(\frac{p}{1-p}\right) \\
\iff p &= \frac{e^{\hat{y}}}{1 + e^{\hat{y}}} = \frac{1}{1 + e^{-\hat{y}}}.
\end{aligned}$$

4. [Optional] Show that the Bayes prediction function $f^*(x)$ for the hinge loss function $\ell(y, f(x)) = \max(0, 1 - yf(x))$ is given by

$$f^*(x) = \text{sign}\left(\pi(x) - \frac{1}{2}\right).$$

Note that it is impossible to recover $\pi(x)$ from $f^*(x)$ in this scenario. However, in practice we work with an empirical risk minimizer, from which we may still be able to recover a reasonable estimate for $\pi(x)$. An early approach to this problem is known as “Platt scaling”: https://en.wikipedia.org/wiki/Platt_scaling.

Solution: Fix x , then we want to find \hat{y} minimizing $r(\hat{y}) = p \max(0, 1 - \hat{y}) + (1-p) \max(0, 1 + \hat{y})$. For $p \in (0, 1)$, this function goes to ∞ as $\hat{y} \rightarrow \pm\infty$. Also, the function is piecewise linear. Thus the function has a minimum and it occurs at a “kink”, or a point of non-differentiability of the function. The “kinks” are at $\hat{y} = -1$ and $\hat{y} = 1$. The function values at these points are $r(1) = 2(1-p)$ and $r(-1) = 2p$. So the minimizer is at $\hat{y} = 1$ if $\frac{p}{1-p} > 1$ and at $\hat{y} = -1$ if $\frac{p}{1-p} < 1$. Otherwise, all $\hat{y} \in [1, 1]$ give equal function values. This is equivalent to saying the minimizer occurs at $\text{sign}(p - \frac{1}{2})$.

3 AdaBoost Actually Works [Optional]

Introduction

Given training set $D = \{(x_1, y_1), \dots, (x_n, y_n)\}$, where y_i ’s are either $+1$ or -1 , suppose we have a weak learner G_t at time t and we will perform T rounds of AdaBoost. Initialize observation weights uniformly by setting $W^1 = (w_1^1, \dots, w_n^1)$ with $w_i^1 = 1$ for $i = 1, 2, \dots, n$. For $t = 1, 2, \dots, n$:

1. Fit the weak learner G_t at time t to training set D with weighting W^t .
2. Compute the weighted misclassification error: $\text{err}_t = \sum_D w_i^t 1(G_t(x_i) \neq y_i) / \sum_i w_i^t$
3. Compute the contribution coefficient for the weak learner: $\alpha_t = \frac{1}{2} \log(\frac{1}{\text{err}_t} - 1)$
4. Update the weights: $w_i^{t+1} = w_i^t \exp(-\alpha_t y_i G_t(x_i))$

After T steps, the cumulative contributions of weak learners is $G(x) = \text{sign}(\sum_{t=1}^T \alpha_t G_t(x))$ as the final output. We will prove that with a reasonable weak learner the error of the output decreases exponentially fast with the number of iterations.

Exponential bound on the training loss

More precisely, we will show that the training error $L(G, D) = \frac{1}{n} \sum_{i=1}^n 1_{\{G(x_i) \neq y_i\}} \leq \exp(-2\gamma^2 T)$ where the error of the weak learner is less than $1/2 - \gamma$ for some $\gamma > 0$. To start, let's denote two cumulative variables: the output at time t as $f_t = \sum_{s \leq t} \alpha_s G_s$ and $Z_t = \frac{1}{n} \sum_{i=1}^n \exp(-y_i f_t(x_i))$.

1. For any function g , show that $1_{\{g(x) \neq y\}} < \exp(-yg(x))$.

SN: When $g(x) = y$ we have $0 < e^{-1}$, when $g(x) \neq y$ we have $1 < e$.

2. Use this to show $L(G, D) < Z_T$

SN:

$$L(G, D) = \frac{1}{n} \sum_{i=1}^n 1_{\{G(x_i) \neq y_i\}} < \frac{1}{n} \sum_{i=1}^n \exp(-y_i G(x_i)) = \frac{1}{n} \sum_{i=1}^n \exp(-y_i f_T(x_i)) = Z_T$$

3. Show that $w_i^{t+1} = \exp(-y_i f_t(x_i))$

SN: Using an inductive argument $w_i^{t+1} = \exp(-y_i \sum \alpha_t G_t(x_i)) = \exp(-y_i f_t(x_i))$.

4. Use part 3 to show $\frac{Z_{t+1}}{Z_t} = 2\sqrt{\text{err}_{t+1}(1 - \text{err}_{t+1})}$ (Hint: use the definition of weight updates and separate the sum on where G_t is equal to 1 and -1 .)

SN:

$$\frac{Z_{t+1}}{Z_t} = \frac{\sum \exp(-y_i f_{t+1}(x_i))}{\sum \exp(-y_i f_t(x_i))} \quad (1)$$

$$= \frac{\sum \exp(-y_i f_t(x_i)) \exp(-y_i \alpha_{t+1} G_{t+1}(x_i))}{\sum \exp(-y_i f_t(x_i))} \quad (2)$$

$$= \frac{\sum w_i^{t+1} \exp(-y_i \alpha_{t+1} G_{t+1}(x_i))}{\sum w_i^{t+1}} \quad (3)$$

$$= \exp(-\alpha_{t+1})(1 - \text{err}_{t+1}) + \exp(\alpha_{t+1})\text{err}_{t+1} \quad (4)$$

$$= \frac{1}{\sqrt{1/\text{err}_{t+1} - 1}}(1 - \text{err}_{t+1}) + \sqrt{1/\text{err}_{t+1} - 1}(\text{err}_{t+1}) \quad (5)$$

$$= 2\sqrt{\text{err}_{t+1}(1 - \text{err}_{t+1})} \quad (6)$$

5. Show that the function $g(a) = a(1 - a)$ is monotonically increasing on $[0, 1/2]$. Show that $1 - a \leq \exp(-a)$. And use the assumption on the weak learner to show that $\frac{Z_{t+1}}{Z_t} \leq \exp(-2\gamma^2)$

SN: $g'(a) = 1 - 2a \geq 0$ on $[0, 1/2]$. Expand e^{-x} in Taylor series. Then,

$$\frac{Z_{t+1}}{Z_t} = 2\sqrt{\text{err}_{t+1}(1 - \text{err}_{t+1})} \quad (7)$$

$$\leq 2\sqrt{(1/2 - \gamma)(1/2 + \gamma)} \quad (8)$$

$$= \sqrt{1 - 4\gamma^2} \quad (9)$$

$$= \exp(-2\gamma^2) \quad (10)$$

6. Conclude the proof!

SN: Since $Z_0 = 1$, write $Z_T = \frac{Z_T}{Z_{T-1}} \frac{Z_{T-1}}{Z_{T-2}} \dots \frac{Z_1}{Z_0}$ which is the missing link.

4 AdaBoost is FSAM With Exponential Loss [Optional]

The AdaBoost score function $G(x) = \sum_{t=1}^T \beta_t G_t(x)$ is a linear combination (actually a conic combination) of functions. (The prediction function is, of course, the sign of the score function.) Forward stagewise additive modeling (FSAM) is another approach to fitting a function of this form.

In FSAM, we have a base hypothesis space \mathcal{H} of real-valued functions $h : \mathcal{X} \rightarrow \mathbf{R}$ and a loss function $\ell(y, \hat{y})$. In FSAM, we attempt to find a linear combination of h 's in \mathcal{H} that minimize the empirical risk. The procedure initializes $f_0(x) = 0$, and then repeats the following steps for $t = 1, \dots, T$:

1. $(\beta_t, h_t) = \operatorname{argmin}_{\beta \in \mathbf{R}, h \in \mathcal{H}} \sum_{i=1}^n \ell(y_i, f_{t-1}(x_i) + \beta h(x_i))$
2. $f_t(x) = f_{t-1}(x) + \beta_t h_t(x)$

Exponential loss and AdaBoost

Consider a generic input space \mathcal{X} , the classification outcome space $\mathcal{Y} = \{-1, 1\}$, the exponential loss function $\ell(y, f(x)) = \exp(-yf(x))$, and an arbitrary base hypothesis space \mathcal{H} consisting of $\{-1, 1\}$ -valued functions. We will show that FSAM in this setting is equivalent to a version of AdaBoost (Algorithm 1) described below. To get this equivalence, we either need to assume that FSAM chooses nonnegative step sizes, i.e. $\beta_t \geq 0$, or we need to assume that \mathcal{H} is symmetric, in the sense that if $h \in \mathcal{H}$, then $-h \in \mathcal{H}$ as well.

1. Write the first step of FSAM using the exponential loss function. In particular, show that the FSAM optimization problem can be written as a minimization of a weighted exponential loss of the step βh :

$$(\beta_t, h_t) = \operatorname{argmin}_{\beta, h \in \mathcal{H}} \left(\frac{1}{\sum_{i=1}^n w_i^t} \right) \sum_{i=1}^n w_i^t \exp(-y_i \beta h(x_i)),$$

where $w_i^t = \exp(-y_i f_{t-1}(x_i))$. (Note that for any t , if we rescale each of w_1^t, \dots, w_n^t by the same constant factor, there is no effect on the arg min. Thus the first factor $(\sum_{i=1}^n w_i^t)^{-1}$ can be dropped. However, we keep it so we can refer to the expression as a **weighted mean**.)

Solution: We have

$$\begin{aligned}
\sum_{i=1}^n \ell(y_i, f_{t-1}(x_i) + \beta h(x_i)) &= \sum_{i=1}^n \exp(-y_i [f_{t-1}(x_i) + \beta h(x_i)]) \\
&= \sum_{i=1}^n \exp(-y_i f_{t-1}(x_i)) \exp(-y_i \beta h(x_i)) \\
&= \sum_{i=1}^n w_i^t \exp(-y_i \beta h(x_i))
\end{aligned}$$

where $w_i^t := \exp(-y_i f_{t-1}(x_i))$, for $i = 1, \dots, n$. Note that this is exactly the exponential loss on the i th example by the ensemble classifier at the previous time step.

2. Define the weighted 0/1 error of h at round t to be

$$\text{err}_t(h) = \left(\frac{1}{\sum_{i=1}^n w_i^t} \right) \sum_{i=1}^n w_i^t 1(y_i \neq h(x_i)).$$

(It's the weights that are specific to round t .) Show that the weighted exponential loss at round t can be written in terms of the weighted 0/1 error. Specifically, show that for any $\beta \in \mathbf{R}$, we have

$$\left(\frac{1}{\sum_{i=1}^n w_i^t} \right) \sum_{i=1}^n w_i^t \exp(-\beta y_i h(x_i)) = e^{-\beta} + (e^{\beta} - e^{-\beta}) \text{err}_t(h).$$

[Hint: Use indicators $1(h(x_i) \neq y_i)$ and $1(h(x_i) = y_i)$ to split the summand on the LHS into pieces. Each piece simplifies, since $y_i, h(x_i) \in \{-1, 1\}$. Then note that $1(h(x_i) = y_i) = 1 - 1(h(x_i) \neq y_i)$.]

Solution: We have

$$\begin{aligned}
\sum_{i=1}^n w_i^t \exp(-\beta y_i h(x_i)) &= e^{-\beta} \sum_{i=1}^n w_i^t 1(y_i = h(x_i)) + e^{\beta} \sum_{i=1}^n w_i^t 1(y_i \neq h(x_i)) \\
&= e^{-\beta} \sum_{i=1}^n w_i^t [1 - 1(y_i \neq h(x_i))] + e^{\beta} \sum_{i=1}^n w_i^t 1(y_i \neq h(x_i)) \\
&= e^{-\beta} \sum_{i=1}^n w_i^t - e^{-\beta} \sum_{i=1}^n w_i^t 1(y_i \neq h(x_i)) + e^{\beta} \sum_{i=1}^n w_i^t 1(y_i \neq h(x_i)) \\
&= e^{-\beta} \sum_{i=1}^n w_i^t + (e^{\beta} - e^{-\beta}) \sum_{i=1}^n w_i^t 1(y_i \neq h(x_i))
\end{aligned}$$

We get the final answer by dividing each side by $\sum_{i=1}^n w_i^t$.

3. We now would like to show that for any fixed “step size” β , the optimal “step direction” h , for which βh minimizes the weighted exponential loss, can be found by minimizing the weighted

0/1 error of h . But more precisely, show that if $\beta \geq 0$ then

$$\operatorname{argmin}_{h \in \mathcal{H}} \left(\frac{1}{\sum_{i=1}^n w_i^t} \right) \sum_{i=1}^n w_i^t \exp(-\beta y_i h(x_i)) = \operatorname{argmin}_{h \in \mathcal{H}} \operatorname{err}_t(h).$$

Also show that if $\beta < 0$ then

$$\operatorname{argmin}_{h \in \mathcal{H}} \left(\frac{1}{\sum_{i=1}^n w_i^t} \right) \sum_{i=1}^n w_i^t \exp(-\beta y_i h(x_i)) = \operatorname{argmin}_{h \in \mathcal{H}} \operatorname{err}_t(-h).$$

Solution: By the previous problem, the argmin problem on the LHS is equivalent to

$$\operatorname{argmin}_{h \in \mathcal{H}} (e^\beta - e^{-\beta}) \operatorname{err}_t(h).$$

This minimization problem is equivalent to $\operatorname{argmin}_{h \in \mathcal{H}} \operatorname{err}_t(h)$ if and only if $e^\beta - e^{-\beta} \geq 0$, which in turn is true if and only if $\beta \geq 0$. This justifies the first claim. If $\beta < 0$, then $e^\beta - e^{-\beta} < 0$ and

$$\begin{aligned} \text{LHS} &= \operatorname{argmin}_{h \in \mathcal{H}} [-\operatorname{err}_t(h)] \\ &= \operatorname{argmin}_{h \in \mathcal{H}} [1 - \operatorname{err}_t(h)] \\ &= \operatorname{argmin}_{h \in \mathcal{H}} \left[1 - \left(\frac{1}{\sum_{i=1}^n w_i^t} \right) \sum_{i=1}^n w_i^t 1(y_i \neq h(x_i)) \right] \\ &= \operatorname{argmin}_{h \in \mathcal{H}} \left[\left(\frac{1}{\sum_{i=1}^n w_i^t} \right) \sum_{i=1}^n w_i^t [1 - 1(y_i \neq h(x_i))] \right] \\ &= \operatorname{argmin}_{h \in \mathcal{H}} \left[\left(\frac{1}{\sum_{i=1}^n w_i^t} \right) \sum_{i=1}^n w_i^t [1(y_i \neq -h(x_i))] \right] \\ &= \operatorname{argmin}_{h \in \mathcal{H}} \operatorname{err}_t(-h) \end{aligned}$$

4. Show that if \mathcal{H} is symmetric, in the sense that $h \in \mathcal{H}$ implies $-h \in \mathcal{H}$, then there is always an optimal FSAM step (β_t, h_t) with $\beta_t \geq 0$. Thus if we assume that either \mathcal{H} is symmetric or FSAM chooses nonnegative step sizes, then we can conclude that

$$h_t = \operatorname{argmin}_{h \in \mathcal{H}} \operatorname{err}_t(h)$$

is a solution to h_t in the minimization problem in the first part, and thus is the FSAM step direction in round t .

Solution: Suppose $(-\beta_t, -h_t)$ is an optimal solution to the FSAM optimization problem, with $\beta_t \geq 0$. Then if \mathcal{H} is symmetric, (β_t, h_t) is also an optimal solution. Thus so long as we assume \mathcal{H} is symmetric or FSAM chooses nonnegative step sizes, then we will have $h_t = \operatorname{argmin}_{h \in \mathcal{H}} \operatorname{err}_t(h)$.

5. Now that we've found h_t , show that the corresponding optimal step size is given by $\beta_t = \frac{1}{2} \log \left(\frac{1 - \text{err}_t}{\text{err}_t} \right)$, where we let $\text{err}_t = \text{err}_t(h_t)$ as a shorthand. [Hint: You'll need to use some differential calculus. Show that what you've found is a minimum by showing that the function you're differentiating is convex.]

Solution: We need to find

$$\begin{aligned}\beta_t &= \operatorname{argmin}_{\beta} \sum_{i=1}^n w_i^t \exp(-\beta y_i h_t(x_i)). \\ &= \operatorname{argmin}_{\beta} [e^{-\beta} + (e^{\beta} - e^{-\beta}) \text{err}_t]\end{aligned}$$

First order condition is

$$\begin{aligned}-e^{-\beta} + (e^{\beta} + e^{-\beta}) \text{err}_t &= 0 \\ -e^{-\beta} [1 - e^{2\beta} \text{err}_t - \text{err}_t] &= 0 \\ e^{2\beta} \text{err}_t + \text{err}_t - 1 &= 0 \\ e^{2\beta} &= \frac{1 - \text{err}_t}{\text{err}_t} \\ \beta &= \frac{1}{2} \log \left(\frac{1 - \text{err}_t}{\text{err}_t} \right)\end{aligned}$$

Note that $e^{-\beta} + (e^{\beta} - e^{-\beta}) \text{err}_t = \text{err}_t e^{\beta} + (1 - \text{err}_t) e^{-\beta}$. Since $\text{err}_t \in [0, 1]$, and since e^{β} and $e^{-\beta}$ are both convex, we have a nonnegative combination of convex functions, which is convex. A local minimum of a convex function is also its global minimum.

6. Show that

$$w_i^{t+1} = \begin{cases} e^{-\beta_t} w_i^t & \text{if } y_i = h_t(x_i) \\ e^{-\beta_t} w_i^t e^{2\beta_t} & \text{otherwise,} \end{cases}$$

[Hint: First show that $w_i^{t+1} = w_i^t \exp(-\beta_t y_i h_t(x_i))$. Then write $y_i h_t(x_i)$ in terms of the indicator function $y_i \neq h_t(x_i)$.]

Solution: We found in the first part that

$$\begin{aligned}w_i^{t+1} &:= \exp(-y_i f_t(x_i)) \\ &= \exp(-y_i [f_{t-1}(x_i) + \beta_t h_t(x_i)]) \\ &= \exp(-y_i f_{t-1}(x_i)) \exp(-y_i \beta_t h_t(x_i)) \\ &= w_i^t \exp(-y_i \beta_t h_t(x_i)) \\ &= w_i^t \exp(-\beta_t [1 - 2 \times 1(y_i \neq h_t(x_i))]) \\ &= w_i^t \exp(-\beta_t) \exp(2\beta_t 1(y_i \neq h_t(x_i)))\end{aligned}$$

7. Let's introduce a specific instance of AdaBoost we'll call "Exact AdaBoost", given in Algorithm 1. The only difference between Exact AdaBoost and AdaBoost is that in Exact AdaBoost,

Algorithm 1: Exact AdaBoost

```
input: Training set  $\mathcal{D} = ((x_1, y_1), \dots, (x_n, y_n)) \in \mathcal{X} \times \{-1, 1\}$ 
 $w_i^1 = 1$  for  $i = 1, \dots, n$  #Initialize weights
for  $t = 1, \dots, T$ :
     $h_t = \arg \min_{h \in \mathcal{H}} \sum_{i=1}^n w_i^t 1(y_i \neq h(x_i))$ 
     $\text{err}_t = \text{err}_t(h_t) = \left( \frac{1}{\sum_{i=1}^n w_i^t} \right) \sum_{i=1}^n w_i^t 1(y_i \neq h(x_i))$ 
     $\alpha_t = \ln \left( \frac{1 - \text{err}_t}{\text{err}_t} \right)$ 
     $w_i^{t+1} = \begin{cases} w_i^t & \text{if } y_i = h_t(x_i) \\ w_i^t e^{\alpha_t} & \text{otherwise,} \end{cases} \quad \text{for } i = 1, \dots, n$ 
return  $f = \sum_{t=1}^T \alpha_t h_t$  #Returns the score function.
(Predictions are  $x \mapsto \text{sign}(f(x))$ ).
```

we require that the base classifier return the best possible $h \in \mathcal{H}$, while in AdaBoost we only vaguely stated that the “base learner fits the weighted training data”, but there was no requirement that the result be the best possible. Indeed, since a typical base classifier is decision trees, and it’s computationally prohibitive to find the best possible tree, Exact AdaBoost is not usually an implementable algorithm. Show that the score functions returned by Exact Adaboost and by FSAM (in our setting) differ only by a constant factor, and of course the hard classifications will be exactly the same.

Solution: From the comment in the first part of this question, we know that for any fixed t , we can multiply all weights by the same factor without changing the FSAM step. Thus we can drop $e^{-\beta_t}$ from the weight update equation. Next, we can set $\alpha_t = 2\beta_t = \log \left(\frac{1 - \text{err}_t}{\text{err}_t} \right)$, at which point our weight updates become

$$w_i^{t+1} = \begin{cases} w_i^t & \text{if } y_i = h_t(x_i) \\ w_i^t e^{\alpha_t} & \text{otherwise.} \end{cases}$$

This is exactly the same as the AdaBoost weight updates. Our step direction at each round is

$$h_t = \arg \min_{h \in \mathcal{H}} \text{err}_t(h),$$

exactly as in Exact AdaBoost. The score function after the T th round are

$$\begin{aligned} f_{\text{FSAM}}^T(x) &= \sum_{t=1}^T \beta_t h_t(x) = \frac{1}{2} \sum_{t=1}^T \alpha_t h_t(x) \\ f_{\text{ExactAdaBoost}}^T(x) &= \sum_{t=1}^T \alpha_t h_t(x), \end{aligned}$$

showing that the score functions differ only by a constant factor.

8. Suppose our ultimate goal is to find the score function returned by FSAM after T rounds in the context described above. Suppose we only have access to an implementation of Exact AdaBoost described in Algorithm 1, and it returns the score function $f(x)$. What would be the score function returned by FSAM?

Solution: It would be $\frac{1}{2}f(x)$, per the solution to the previous problem.

5 [Optional] Decision Tree Implementation

In this problem we'll implement decision trees for both classification and regression. The strategy will be to implement a generic class, called `Decision_Tree`, which we'll supply with the loss function we want to use to make node splitting decisions, as well as the estimator we'll use to come up with the prediction associated with each leaf node. For classification, this prediction could be a vector of probabilities, but for simplicity we'll just consider hard classifications here. We'll work with the classification and regression data sets from Homework #4.

1. [Optional] Complete the class `Decision_Tree`, given in the skeleton code. The intended implementation is as follows: Each object of type `Decision_Tree` represents a single node of the tree. The depth of that node is represented by the variable `self.depth`, with the root node having depth 0. The main job of the fit function is to decide, given the data provided, how to split the node or whether it should remain a leaf node. If the node will split, then the splitting feature and splitting value are recorded, and the left and right subtrees are fit on the relevant portions of the data. Thus tree-building is a recursive procedure. We should have as many `Decision_Tree` objects as there are nodes in the tree. We will not implement pruning here. Some additional details are given in the skeleton code.
2. [Optional] Complete either the `compute_entropy` or `compute_gini` functions. Run the code provided that builds trees for the two-dimensional classification data. Include the results. For debugging, you may want to compare results with sklearn's decision tree. For visualization, you'll need to install `graphviz`.
3. [Optional] Complete the function `mean_absolute_deviation_around_median` (MAE). Use the code provided to fit the `Regression_Tree` to the `krr` dataset using both the MAE loss and median predictions. Include the plots for the 6 fits.

6 Gradient Boosting Implementation

This method goes by many names, including gradient boosting machines (GBM), generalized boosting models (GBM), AnyBoost, and gradient boosted regression trees (GBRT), among others. Although one of the nice aspects of gradient boosting is that it can be applied to any problem with a subdifferentiable loss function, here we'll keep things simple and consider the standard regression setting with square loss.

1. Complete the `gradient_boosting` class. As the base regression algorithm, you should use the regression tree from the previous problem, if you completed it. Otherwise, you may use sklearn's regression tree. You should use the square loss for the tree splitting rule and the mean function for the leaf prediction rule. Run the code provided to build gradient boosting

models on the classification and regression data sets, and include the plots generated. Note that we are using square loss to fit the classification data, as well as the regression data.

2. [Optional] Repeat the previous runs on the classification data set, but use a different classification loss, such as logistic loss or hinge loss. Include the new code and plots of your results. Note that you should still use the same regression tree settings for the base regression algorithm.
